ABSTRACT

Most investors and real estate developers consider Brownfield projects risky and, to compensate for environmental risk, demand higher returns on the investment needed to cleanup a contaminated property. The risk perception is aggravated by the fact that remediation of a contaminated site takes time, during which, real estate market conditions may change significantly.

To estimate the value of a redeveloped Brownfield property considering the environmental and market risks, both technical and market risks are integrated. A closed-form solution derived for a perpetual American call option was modified to calculate the optimal sequential investment that accounts for the time required to undertake the investment. The proposed solution can be used to value a Brownfield property if the owner has the option to delay remediation indefinitely, while waiting for optimal conditions. The results of the proposed approximation are compared to the results obtained using numerical techniques to solve partial differential equations.

I. INTRODUCTION

Quantification of risk and economic cost associated with actual and/or potential environmental pollution is central to the success of Brownfields redevelopment. The term Brownfields refers to abandoned, idled, or underutilized environmentally impaired properties. A Brownfields redevelopment includes cleaning up the site so that it can be returned to a productive use for residential, commercial, and/or industrial purposes. As is the case with any construction project, remediation of a contaminated site takes time to complete. Different from typical construction projects, real estate transactions that include cleanup of a contaminated property are usually considered risky by most investors and demand a higher return on investment in order to take on the project, and the rate of return demanded for each project depends upon each investor's risk preference.

Although remediation of contaminated sites in the United States is enforced by local or federal agencies, many sites are cleaned up voluntarily without a specific timetable. This may be the case for the owners/developers who are not responsible for the site contamination and have purchased the property with the intent to redevelop it as soon as real estate conditions are appropriate. For these situations, voluntary cleanup (remediation) of contaminated properties can be viewed as a perpetual American call option on the clean property; that is, the owner or developer has the right, but not the obligation, to pay a total sunk remediation cost in return for a real estate project (clean property).

II. PRELIMINARY FORMULATION

Because remediation of a contaminated site takes time, as is the case with any investment project, a straightforward application of the solution to the perpetual American call option (Samuelson, 1965) cannot be applied. The solution to this problem was provided by Majd and Pindyck (1987). They analyzed the problem of investing continuously and optimally until the project is complete, assuming that investment can be stopped and restarted at no cost.

The value of the clean property (V) is assumed to follow a geometric Brownian motion process of the form:

$$dV = \alpha V dt + \sigma V dz \tag{1}$$

where α is the expected rate of growth; σ is the uncertainty associated to the value of the clean property; dz is the differential of a standard Wiener process (with mean 0 and variance dt). The exercise price (i.e., the total remaining remediation cost, K) is spent over a period of time at a maximum rate of k. The total remaining remediation cost (K) and the rate of expenditure (k) are related as follows:

$$dK = \begin{cases} -kdt & \text{for } V \ge V^*(K) \\ 0 & \text{otherwise} \end{cases}$$
(2)

where $V^*(K)$ represents the optimal investment value of the clean property as a function of the remaining remediation cost. Equation (2) indicates that investment only takes

place if the value of the clean property is greater than the optimal value, $V^*(K)$, which needs to be obtained as part of the solution. The investment problem described above can be written in a partial differential form as:

for V < V^{*}(K):
$$\frac{1}{2}\sigma^2 V^2 \frac{\partial^2 C}{\partial V^2} + (r - \delta) V \frac{\partial C}{\partial V} - rC = 0$$
 (3a)

for
$$V \ge V^*(K)$$
: $\frac{1}{2}\sigma^2 V^2 \frac{\partial^2 C}{\partial V^2} + (r-\delta)V \frac{\partial C}{\partial V} - rC - k \frac{\partial C}{\partial K} - k = 0$ (3b)

where C is the option value of the clean property; r is the risk-free discount rate; $\delta = \mu - \alpha \ (\mu > \alpha)$ is the opportunity cost; μ is the market risk-adjusted expected rate of return from owning the property; K is the total remaining expenditure; k is the rate of expenditure. Equation (3a) can be solved analytically, whereas Equation (3b) must be solved numerically using finite different techniques (e.g., Majd and Pindyck, 1987).

III. APPROXIMATE SOLUTION

As discussed above, voluntary cleanup (remediation) of contaminated properties can be viewed as a perpetual American call option on the clean property; that is the owner or developer has the right, but not the obligation, to pay a total sunk remediation cost (K) spent for a certain rate of return for a real estate project (clean property) having the current value of V (V is stochastic and changes with time). If the remediation cost is assumed to be spent instantaneously, the closed-form solution for the perpetual American call option on a dividend-paying stock derived by Samuelson (1965) could be used to estimate the value of the investment:

$$\beta = \frac{1}{2} - \frac{(r-\delta)}{\sigma^2} + \sqrt{\left(\frac{(r-\delta)}{\sigma^2} - \frac{1}{2}\right)^2 + \frac{2r}{\sigma^2}}$$
(4)

$$V^* = \frac{\beta}{\beta - 1} K_0 \tag{5}$$

$$A = \frac{V^* - K_o}{(V^*)^{\beta}} \tag{6}$$

$$C(V) = \begin{cases} V_o - K_o & \text{for } V \ge V^*(K) \\ AV_o^\beta & \text{otherwise} \end{cases}$$
(7)

In order to use the closed-form solution derived for the American perpetual call option given by Equations (4) through (7), equivalent investment cost and value of the real estate investment need to be used. The expressions that were found to provide consistently equivalent results of the optimal value of the real estate investment and the option are: (i) the present value of the total remediation cost; and (ii) the present value of the real estate investment. The present value of the investment cost (K_o) is obtained assuming that investment is made continuously over the time period T = K/k such that:

$$K_{0} = \int_{0}^{1} k e^{-rt} dt = (1 - e^{-rK/k}) \frac{k}{r}$$
(8)

Similarly, the present value of the real estate investment (V_o) is obtained assuming that investment cost is made continuously over the time period T = K/k until the remediation is completed. The present value of the completed project (i.e., cleaned property) V that is expected to grow at a rate α can be estimated as using the discount rate μ as:

$$V_{o} = \left(V e^{\alpha K/k} \right) e^{-\mu K/k} = V e^{-\delta K/k}$$
(9)

Equations (8) and (9) can be used together with Equations (4) through (7) to obtain the value of an investment that takes time to build.

IV. VALIDATION

Equations (4) through (9) can be used to evaluate the option value of an asset that takes time to build (e.g., the remediation of a contaminated site). In this section, the proposed simplified equations are validated against the results of the more rigorous numerical solution provided by Majd and Pindyck (1987). Table 1 shows the results of the value of the option to invest (C) assuming an annual risk-free rate r = 2%, annual rate of opportunity cost $\delta = 6\%$, and annual standard deviation $\sigma = 20\%$, a rate of expenditure k = 1 million/year, for K = 1, 2, 3, 4, 5, and 6 million and selected values of V (i.e., values are selected from Majd and Pindyck, 1987). Table 1 also shows the results from Majd and Pindyck (1987) (in italics), obtained using numerical finite difference techniques. As shown in the table, the results of the proposed approximate solution agree with the numerical results. The average error between the two sets of results shown in Table 1 is 0.79%.

According to the results provided by the finite difference solution and summarized in Table 1, for a total remaining remediation cost of K = \$3 million, investment should continue if the value of the real estate (V) is greater than $V^* = 5.21 million (i.e., the optimal option value $C^* = 1.42 million). A value of C(V = 5.21, K = 3) = \$1.44 million using the approximate solution is shown in Table 1 (i.e., a 1.5% difference with the numerical solution). This value, however, does not correspond to the optimal call option value, as discussed below.

Value of Completed Project, V (millions)	Total Remaining Investment (K), millions					
	6	5	4	3	2	1

Table 1Option investment value, C1,2

1 Values in italics were obtained from Majd and Pindyck (1987).

2

Values in **bold** and *italic* represent the optimal investment value, *C**, that corresponds to each value of *K*. That is, investment takes place only if *V* is greater than the corresponding optimal value.

The values of the optimal call option value, C^* can be calculated using Equations (4) through (9). For instance, for a total remaining remediation cost of K = \$3 million, using Equations (5) and (7), the value of the optimal real estate investment and the corresponding option value are $V^* = \$5.0$ million and $C^* = \$1.26$ million, respectively. For this case, the difference between the option values calculated using the approximate solution and the numerical scheme is \$0.16 million (i.e., that is 12.7%) whereas the difference between the optimal real estate investment is \$0.21 million (i.e., that is 4.8%). A comparison of the optimal call option values (C*) for each value of total remaining cost (K) obtained using the proposed approximated solution and the results from the numerical solution by Majd and Pindyck (1987), is presented in Figure 1.

Although the calculated option value for each pair (V,K) in Table 1 agrees with those calculated using the numerical finite difference scheme, as shown in Figure 1, the optimal option value may not be accurately calculated using the numerical algorithm scheme.

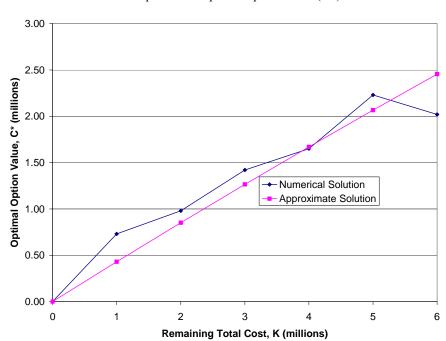

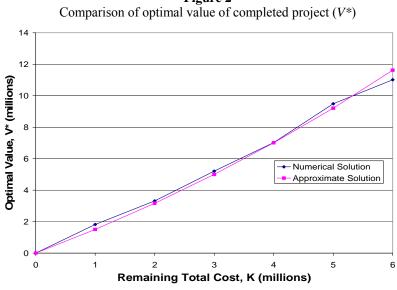

Figure 1 Comparison of optimal option value (*C**)

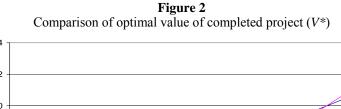

The main reason for the discrepancy is that the calculated values of the option C(V,K) using the numerical algorithm are obtained at the discrete values of V shown in Table 1, may not necessarily include the optimal values V*. Each of the values of V selected for the numerical analysis was obtained as follows (Majd and Pindyck, 1987):

$$V = e^{0.15j}$$
(10)

for j = 0, 1, 2, ...25. It follows from Equation (10) that as j grows, the increment in V grows exponentially. A better agreement would likely be obtained if a finer mesh is used for the finite different scheme.

On the other hand, as shown in Figure 2, the agreement between the calculated optimal value of the completed real estate project using the approximate solution and the numerical finite different scheme is very good. Therefore, the optimal value for starting the remediation project can be reasonably estimated using the approximate solution presented in this paper.

v. APPLICATION

For the environmental application discussed herein, the proposed modified American perpetual option presented in this paper can be used to answer the following questions:

- 1. What is the value of a real estate investment (call option value, C*) if the property is contaminated and a prospective seller or buyer can remediate it at any time?
- What is the optimal value of the project (V^*) at which a developer should start 2. remediation of the site and pay the remediation cost, K, over a period of time?
- 3. How are these values affected if the remediation cost is uncertain?

Assuming that the average cost to remediate the contaminated property is \$5 million, the current value of the clean property is \$6 million, the market volatility of the real estate project is 20%, the interest rate is 2%, the average time to redevelop is 3 years, and the project revenue stream, once it is completed, is 6% of the current value, using Equations (4) through (9), the estimated value of the optimal investment (V^*) and the option to wait are \$6.96 and \$0.71, respectively. Because the current value of the property is \$6 million, it is optimal to wait.

Remediation projects are uncertain regarding cost and time to implement the remediation. In general, a probability distribution can be estimated based on technical information of the site and the remediation technique selected. These uncertainties can be integrated into the uncertainty of the market value of the clean property using the model presented in this paper along with Monte Carlo simulations. To this end, the commercial software Crystal BallTM is used to conduct the simulations. For this case, the remediation cost and the time to complete the remediation project are both

considered random correlated variables log normally distributed with a mean (and standard deviation) values of \$5 (\$2.35) million and 3 (1.2) years, respectively, and a coefficient of correlation of 0.8 (Figures 3 and 4). The uncertainty associated with the real estate market is already accounted for in Equations (4) through (9).

Figure 4 Probability Distribution for Time to Completion

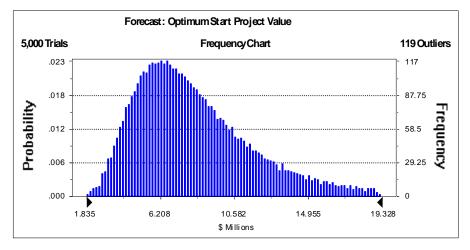

Figure 5 Probability distribution for optimum project value (V^{*})

Forecast: Land Value 5,000 Trials Frequency Chart 3 Outliers .014 71 .011 53.25 Probability requency .007 35.5 .004 17.75 dluu 0 .000 3.65 7.24 0.06 1.85 5.45 \$ millions

Figure 6 Probability distribution for option value

The calculated optimal value to start the remediation project has the distribution shown in Figure 5 having a mean of \$8.6 million and a standard deviation of \$4.4 million. The optimal net present value of the contaminated property (i.e., the perpetual American call option) is \$3.1 million (Figure 6) having a standard deviation of \$1.7 million (assuming that the developer can wait for this optimal value). For this case, because the uncertainty in the remediation cost and the time to complete is high, the optimal value to start remediating the site is about 23% higher than the case without

uncertainty of these parameters. Thus, as expected, technical uncertainty favors delaying the project.

VI. CONCLUSIONS

A simplified model to calculate the optimal option value for projects that require time to implement has been presented in this paper. The results of the simplified model have been successfully compared to the results obtained using numerical techniques. For the environmental application discussed herein, the proposed modified American perpetual option presented in this paper can be used to answer questions regarding the value of Brownfields projects, taking into consideration technical and market uncertainty.
